20 Here we use Illumina whole-genome sequence data from phase 1 of the *Anopheles*
21 *gambiae* 1000 Genomes Project (Ag1000G) to provide a comprehensive account of
22 genetic variation at the *Vgsc* locus in mosquito populations from 8 African countries.
23 In addition to three known resistance variants, we describe 20 non-synonymous vari-
24 ants at appreciable frequency in one or more populations that are previously unknown
25 in mosquitoes. For each variant we predict a resistance phenotype based on genetic
26 evidence for positive selection, patterns of linkage between variants, and functional
27 evidence from other species. We then analyse the genetic backgrounds on which re-
28 sistance variants are found, to refine our understanding of the origins and spread
29 of resistance between species and geographical locations. We identify ten distinct
30 outbreaks of resistance, of which five appear to be localised to a single geographical
31 location, and five have spread between two or more countries. The most successful
32 and widespread outbreak (F1) originates in West Africa and has subsequently spread
33 to countries in Central and Southern Africa. Our results demonstrate that the molec-
34 ular basis of pyrethroid resistance in African malaria vectors is more complex than
35 previously appreciated, and provide a foundation for the design of new genetic tools
36 for outbreak surveillance to inform insecticide resistance management and track the
37 further spread of resistance.

38 Introduction

39 Pyrethroid insecticides are currently the cornerstone of malaria prevention in Africa [1].
40 Pyrethroids continue to be the only approved class of insecticide for use in insecticide-
41 treated bed-nets (ITNs), and are widely used in indoor residual spraying (IRS) campaigns
42 as well as in agriculture. Pyrethroid resistance is, however, now widespread in malaria vec-
43 tor populations across Africa [2]. The World Health Organisation (WHO) has published
44 plans for insecticide resistance management (IRM), which highlight the need for improve-
45 ments in our ability to monitor resistance, and for improvements in our understanding of
46 the molecular mechanisms of resistance [3].

47 The voltage-gated sodium channel (VGSC) is the physiological target of pyrethroid in-
48 secticides, and is integral to the insect nervous system. Pyrethroid molecules bind to sites
49 within the protein channel and prevent normal nerve function, causing paralysis (“knock-
50 down”) and then death. However, amino acid substitutions at key positions within the

51 protein alter the interaction with insecticide molecules, increasing the dose of insecticide re-
52 quired for knock-down (target-site resistance) [4]. In the African malaria vectors *Anopheles*
53 *gambiae* and *An. coluzzii*, three substitutions have been found to cause pyrethroid resis-
54 tance. Two of these substitutions occur in codon 995¹, with L995F prevalent in West and
55 Central Africa [5, 6], and L995S found in Central and East Africa [7, 6]. A third variant,
56 N1570Y, was found in Central Africa and shown to increase resistance in association with
57 L995F [9]. However, studies in other insect species have found a variety of other *Vgsc*
58 substitutions inducing a resistance phenotype [10, 11, 12]. To our knowledge, no studies
59 (prior to Ag1000g [13]) in malaria vectors have analysed the full *Vgsc* coding sequence,
60 thus the genetic basis of target-site resistance to pyrethroids has not been fully explored.

61 Basic information is also lacking about the history and epidemiology of pyrethroid re-
62 sistance in malaria vectors. For example, it is not known when, where or how many times
63 VGSC mediated pyrethroid resistance has emerged. The paths of transmission carrying
64 resistance between mosquito populations are also not known. Previous studies have found
65 evidence that L995F occurs on several different genetic backgrounds, suggesting multiple
66 independent outbreaks of resistance driven by this allele [14, 15, 16]. However, these stud-
67 ies analysed only a small region of the VGSC gene, and therefore had limited power to
68 make inferences about the origins or spread of resistance alleles. It has also been shown
69 that the L995F allele spread from *An. gambiae* to *An. coluzzii* in West Africa [17, 18].
70 However, both L995F and L995S now have wide geographical distributions [6], and no
71 attempts have been made to reconstruct the geographical spread of either allele. If in-
72 secticide resistance were a disease, standard methods of outbreak investigation could be
73 applied, and information about epidemiological origins, transmission and virulence fac-
74 tors would be used to formulate an outbreak response plan. In the absence of analogous
75 information for pyrethroid resistance, planning an effective response is clearly difficult.

76 Here we report an in-depth analysis of the VGSC gene, using whole-genome Illumina se-
77 quence data from phase 1 of the *Anopheles gambiae* 1000 Genomes Project (Ag1000G) [13].
78 We investigate variation across the complete gene coding sequence, to fully characterise
79 the primary and secondary genetic factors driving target-site resistance to pyrethroids

¹Codon numbering is given here relative to transcript AGAP004707-RA as defined in the AgamP4.4 gene annotations. A mapping of codon numbers from AGAP004707-RA to *Musca domestica*, the system in which the *kdr* mutations were first discovered [8], is given in Table 1 and in @@Supplementary data.

80 in natural mosquito populations. We then use haplotype data from the chromosomal
81 region spanning the VGSC gene to study the genetic backgrounds carrying resistance al-
82 leles. The goal of these analyses is to diagnose how many separate outbreaks of target-site
83 pyrethroid resistance have occurred, which outbreaks are localised, and which are spread-
84 ing. We also explore ways in which variation data from Ag1000G could be used to design
85 high-throughput, low-cost genetic assays for monitoring pyrethroid resistance, with the
86 capability to differentiate and track separate resistance outbreaks. Finally, we investigate
87 the potential of these data to reconstruct the path of transmission of resistance alleles be-
88 tween mosquito populations, and to provide information on the probable source. Although
89 the geographical and temporal sampling of mosquito populations in Ag1000G phase 1 is
90 too sparse to support a comprehensive outbreak analysis, our aim is to investigate meth-
91 ods that could provide answers to these questions, given further sequencing of mosquito
92 populations.

93 **Results**

94 **Functional variation**

95 To identify variants with potentially functional roles in pyrethroid resistance, we extracted
96 single nucleotide polymorphisms (SNPs) from the Ag1000G phase 1 data resource that
97 alter the amino acid sequence of the VGSC protein, and computed their allele frequencies
98 among 9 populations defined by species and country of origin. Alleles that confer resistance
99 are expected to increase in frequency under selective pressure, and we refined the list
100 of potentially functional variant alleles to retain only those at an appreciable frequency
101 ($>5\%$) in one or more populations (Table 1). The resulting list comprises 23 variant alleles,
102 including the known L995F, L995S and N1570Y variants, and a further 20 not previously
103 described in these species. We reported 15 of these novel alleles in our initial analysis of
104 the Ag1000G phase 1 data [13], and we extend the analyses here to incorporate a SNP
105 which alters codon 1603 and the tri-allelic SNPs at codons 402 and 490.

106 The two alleles in codon 995 are clearly the main drivers of resistance at this locus.
107 The L995F allele at high frequency in populations of both species from West, Central and
108 Southern Africa, and the L995S allele at high frequency among *An. gambiae* populations

Table 1. Non-synonymous nucleotide variation in the voltage-gated sodium channel gene. AO=Angola; BF=Burkina Faso; GN=Guinea; CM=Cameroon; GA=Gabon; UG=Uganda; KE=Kenya; GW=Guinea-Bissau; *Ac=An. coluzzii*; *Ag=An. gambiae*. All variants are at 5% frequency or above in one or more of the 9 Ag1000G phase 1 populations, with the exception of 2,400,071 G>T which is only found in the CMAg population at 0.4% frequency but is included because another mutation (2,400,071 G>A) is found at the same position causing the same amino acid substitution (M490I); and 2,431,019 T>C (F1920S) which is at 4% frequency in GAAG but also found in CMAg and linked to L995F.

from Central and East Africa (Table 1; [13]). All haplotypes carrying L995F or L995S have evidence for strong recent positive selection [13]. 289 samples in the dataset carried ≥ 1 L995F alleles of which 92 were homozygotes and in the case of L995S, 156 samples carried ≥ 1 alternative alleles and of these 38 were homozygotes; the resistance phenotype at this locus is thought to be incompletely recessive [19]. Both alleles were present in populations sampled from Cameroon and Gabon, including some individuals with a hybrid L995F/S genotype (46/275 samples in Cameroon, 36/56 in Gabon). In Cameroon these alleles were in Hardy Weinberg equilibrium ($\chi^2 = 0.02$, $p > 0.05$), thus there does not appear to be selection for, or against, heterozygote carriers of both alleles; however in Gabon, they were not in equilibrium ($\chi^2 = 8.96$, $p < 0.005$), with an excess of heterozygotes suggesting there may be a fitness advantage to mosquitoes carrying both alleles in this region.

¹ Position of the variant within the protein. IN=internal domain; TM=trans-membrane domain. The protein contains four homologous repeats (I-IV), each having six transmembrane segments (1-6). Codes in parentheses identify the specific domain, e.g., “I.S4” refers to trans-membrane segment 4 in repeat I, and “IS4-IS5” refers to the linker segment between I.S4 and I.S5.

² Phenotype predictions are based on population genetic evidence and have not been confirmed experimentally.

³ Literature search results for experimental evidence, assoc. - association study, *in vitro* - *Xenopus* oocytes.

⁴ Publication from which evidence is taken.

120 The I1527T allele is present in *An. coluzzii* from Burkina Faso at 14% frequency, and
 121 there is evidence that haplotypes carrying this allele have been positively selected [13].
 122 Codon 1527 occurs within trans-membrane domain segment III.S6, immediately adjacent
 123 to a second predicted binding pocket for pyrethroid molecules, thus it is plausible that
 124 I1527T could alter insecticide binding [12]. We also found that the two variant alleles
 125 affecting codon 402, both of which induce a V402L substitution, were in strong linkage
 126 with I1527T ($D' \geq 0.8$; Figure 1), and almost all haplotypes carrying I1527T also carried a
 127 V402L substitution. The most parsimonious explanation for this pattern of linkage is that
 128 the I1527T mutation occurred first, and mutations in codon 402 subsequently arose on this
 129 genetic background. Codon 402 also occurs within a trans-membrane segment (I.S6), and
 130 the V402L substitution has associated with pyrethroid resistance in bedbugs [20]. Other
 131 substitutions at this locus have also been associated with resistance, V402A/G in the moth
 132 crop pests *Helicoverpa zea* [21] and V402M in *Heliothis virescens*, the latter of which has
 133 been shown experimentally to confer resistance in *Xenopus* oocytes [22, 23]. However,
 134 because V402L appears secondary to I1527T in our cohort, we classify I1527T as a putative
 135 resistance driver and V402L as a putative enhancer. Because of the limited geographical
 136 distribution of these alleles, we hypothesize that the I1527T+V402L combination represents
 137 a pyrethroid resistance allele that arose in West African *An. coluzzii* populations; however,
 138 the L995F allele is at higher frequency (85%) in our Burkina Faso *An. coluzzii* population,
 139 and is known to be increasing in frequency [24], therefore L995F may provide a stronger
 140 resistance phenotype and is replacing I1527T+V402L in these populations.

141 Of the other 16 SNPs, 13 occurred almost exclusively in combination with L995F (Figure
 142 1; [13]). These include the N1570Y allele, known to enhance pyrethroid resistance in *An.*
 143 *gambiae* in combination with L995F [9]. These also include two variants in codon 1874
 144 (P1874S, P1874L). P1874S has previously been found in a colony of the crop pest *Plutella*
 145 *xylostella* with a pyrethroid resistance phenotype, but has not been shown to confer re-
 146 sistance experimentally [27]. 10 of these variants, including N1570Y and P1874S/L, occur
 147 within internal linker domains of the protein, and so fit the model of variants that may en-
 148 hance or compensate for the driver phenotype by modifying channel gating behaviour [28,
 149 9]. The remaining 3 variants are within trans-membrane domains, and so may enhance
 150 resistance by altering or interacting with the insecticide binding sites on the VGSC [12].

Figure 1. Linkage disequilibrium between non-synonymous variants. A value of 1 indicates that the two variants always occur in combination, and conversely a value of -1 indicates that the two variants never occur in combination. @TODO nuance this?

151 Because of the tight linkage between these 13 SNPs and the L995F allele, we classify all as
152 putative L995F enhancers, although experimental work is required to confirm a resistance
153 phenotype.

154 The remaining 3 variants (M490I, A1125V, V1254I) do not occur in combination with
155 any known resistance allele, and do not appear to be associated with haplotypes under
156 selection [13] A possible exception is the M490I allele found at 18% frequency in the Kenyan
157 population, although the fact that this population has experienced a recent population
158 crash makes it difficult to test for evidence of selection at this locus. All 3 variants occur
159 in internal linker domains, and so do not fit the model of a resistance driver, although
160 experimental work is required to rule out a resistance phenotype.

161 Haplotype structure

162 Although it is known that pyrethroid resistance is increasing in prevalence in malaria
163 vector populations across Africa, it has not been clear whether this is being driven by the
164 spread of resistance alleles via gene flow, or by resistance alleles emerging independently in
165 multiple locations, or by some combination of both processes. The Ag1000G data resource
166 provides a potentially rich source of information about the evolutionary and demographic
167 history of insecticide resistance in any given gene, because data are available not only for
168 SNPs in gene coding regions, but also SNPs in introns and flanking intergenic regions,
169 and in neighbouring genes. These additional variants can be used to analyse the genetic
170 backgrounds (haplotypes) on which resistance alleles are found. In sexually reproducing
171 species, DNA sequences are transmitted from parents to progeny in chunks, rearranged via
172 recombination at each generation, and haplotypes convey information about this history
173 of transmission and recombination, especially when haplotypes from many individuals can
174 be compared.

175 In our initial analysis of the *Vgsc* (@@REF Ag1000G), we used 1710 biallelic SNPs
176 from within the @@70 kbp *Vgsc* gene (@@N exonic, @@N intronic) to compute the num-
177 ber of SNP differences between all pairs of 1530 haplotypes derived from 765 wild-caught
178 mosquitoes. This genetic distance measurement is a rough proxy for the degree of re-
179 latedness between haplotypes, in the sense that two haplotypes with a small number of
180 SNP differences must be closely related and share a common ancestor in the recent past.
181 This measurement cannot be used to directly estimate the time to most recent common
182 ancestor (TMRCA) for any pair of haplotypes, however, because it does not account for
183 the possibility of recombination events within the gene, which is increasingly likely for
184 pairs of haplotypes that are more distantly related. Nevertheless, it provides a useful tool
185 for exploring patterns of similarity and dissimilarity within the data. To visualise these
186 patterns, we used the pairwise genetic distances to perform hierarchical clustering, which
187 groups similar haplotypes together into clusters. We found that haplotypes carrying resis-
188 tance alleles were grouped into 10 distinct clusters. Five of these clusters carried the L995F
189 allele (labelled F1-F5), and a further five clusters carried L995S (labelled S1-S5). Within
190 each cluster, haplotypes were nearly identical across all 1710 SNPs (spanning @@70 kbp),

and therefore each cluster represents a collection of haplotypes with a very recent common ancestor. Within some of these clusters, we found haplotypes from mosquitoes collected from different locations. Specifically, cluster F1 contained haplotypes from Guinea, Burkina Faso, Cameroon and Angola; clusters @@ each contained haplotypes from Cameroon and Gabon; and cluster @@ contained haplotypes from Uganda and Kenya. The F1 cluster also contained haplotypes from both *An. gambiae* and *An. coluzzii* individuals. If we assume that haplotypes within each cluster share a common ancestor since the introduction of insecticides, which is reasonable given the high degree of similarity, then each of these clusters provides evidence that resistance alleles have been spreading between geographical locations and species via adaptive gene flow. Here we present several new analyses of these haplotype data, to confirm our initial inferences regarding gene flow, and provide further details regarding the origins and movement of resistance alleles.

To provide an alternative view of the genetic similarity between haplotypes carrying resistance alleles, we used haplotype data from within the *Vgsc* gene region to construct

Figure 2. Haplotype networks. @@TODO caption

205 median-joining networks (Figure 2). This analysis is very similar to hierarchical cluster-
 206 ing, except that it allows for the reconstruction and placement of intermediate haplotypes
 207 that may not be observed in the data. We constructed these networks up to a maximum
 208 distance of 2 SNP differences, to ensure that each connected component in the result-
 209 ing networks represents a collection of haplotypes with a recent common ancestor, and
 210 thus which is also likely to be minimally affected by recombination within the gene. For
 211 haplotypes carrying L995F, the resulting network confirms the presence of five distinct
 212 clusters, with close correspondance to the clusters F1-F5 identified previously. The L995S
 213 network also confirms five distinct clusters, in concordance with our previous analysis.

214 The haplotype networks bring into sharp relief the explosive evolution of amino acid
 215 substitutions secondary to the L995F allele. Within the F1 network, nodes carrying non-
 216 synonymous variants radiate out from a central node carrying only L995F, indicating that
 217 the central node represents the ancestral haplotype carrying L995F alone which initially
 218 came under selection, and these secondary variants have arisen subsequently as new mu-
 219 tations. Many of the nodes carrying secondary variants are large, consistent with positive
 220 selection and a functional role for these secondary variants as enhancers of the L995F re-
 221 sistance phenotype. The F1 network also allows us to infer multiple introgression events
 222 between the two species. The central (ancestral) node comprises haplotypes from both
 223 species, as do nodes carrying the N1570Y, P1874L, and 1 more variant.
 224 This structure is consistent with an initial introgression of the ancestral F1 haplotype, fol-
 225 lowed by introgression of haplotypes carrying secondary mutations. The contrast between
 226 the haplotype networks for the L995F and L995S alleles is striking because of the near-
 227 total absence of non-synonymous variation within the L995S networks. As we reported
 228 previously, this difference is highly significant – the ratio of non-synonymous to synony-
 229 mous nucleotide diversity (d_{NS}/d_S) is 1.5 times higher among haplotypes carrying
 230 L995F relative to haplotypes carrying L995S (Test; $P=0.001$) (REF Ag1000G). Some
 231 secondary variants are present within the L995S networks, but all are at low frequency,
 232 and thus may be neutral or mildly deleterious variants that are hitch-hiking on selective
 233 sweeps for the L995S allele.

234 While the haplotype clustering and network analyses provide evidence for the spread
 235 of resistance alleles via adaptive gene flow, and for the secondary evolution of L995F

enhancer alleles, they have several limitations. Within haplotype clusters where gene flow has occurred, they have poor resolution to infer the origin and direction of gene flow. This is because the analyses only leverage information about genetic distance within the *Vgsc* gene, and for very recent events, insufficient time has elapsed for informative mutations to accumulate within this relatively small genome region. Also, the fact that we observe five distinct clusters for each of the codon 995 alleles suggests that each cluster is in some sense independent from the others, and thus gene flow is not required for resistance to emerge in multiple geographical locations. However, the threshold for the genetic distance at which we have chosen to divide haplotypes into different networks or clusters is to a certain extent arbitrary, and based on an intuitive sense of how much variation could have accumulated among the descendants of a single resistant ancestor since the onset of selective pressure. We also need to clarify what we mean by “independent”, as there are several possible scenarios under which resistance could evolve in multiple populations in the absence of gene flow. Finally, analyses of genetic distance within a fixed genome region can be confounded by recombination events occurring within that region. For example, a recombination event within the *Vgsc* gene upstream of codon 995 could cause us to split a collection of haplotypes into two clusters, even though they are ancestrally related within the region downstream of the recombination event. In the next sub-sections we provide some conceptual foundations to help clarify these ambiguities, and use analyses of haplotype sharing from the genome regions flanking the *Vgsc* gene to provide finer resolution to diagnose recent gene flow events.

Insecticide resistance outbreaks

To provide an aid to further interpretation of the genetic data, and relating them to the challenges of insecticide resistance management, we introduce the concept of an **insecticide resistance outbreak**. Informally, we define a resistance outbreak by analogy with the epidemiological concept of an outbreak, as a rapid increase in the prevalence of insecticide resistance among mosquitoes at a particular place and time. Note that this does not imply that the overall abundance of mosquitoes is increase, just that the relative frequency of resistance within mosquito populations is increasing. We also require that all occurrences of insecticide resistance within the same outbreak are connected

266 by a chain of transmission of resistance alleles from parent to progeny mosquitoes, and
 267 thus can be traced back to a single resistant common ancestor. A resistance outbreak
 268 can be **localised**, meaning that it affects a small group of mosquitoes of a single species
 269 from a limited geographical area. Alternatively, a resistance outbreak may be **spreading**,
 270 meaning that resistance alleles have been transmitted since the introduction of insecti-
 271 cides by interbreeding of mosquitoes of different species and/or originating from different
 272 geographical locations.

273 Our goal for the *Vgsc* gene can now be restated, which is to perform an insecticide
 274 resistance outbreak analysis. We would like to diagnose how many separate outbreaks have
 275 occurred, which outbreaks are localised, and which are spreading. For spreading outbreaks,
 276 we would like to reconstruct the path of transmission of resistance alleles between mosquito
 277 populations, and to provide information on the probable source. We would, of course, also
 278 like to identify the primary and secondary genetic factors that are driving each outbreak.
 279 Stated in this way, it is easier to discuss how this information is potentially relevant
 280 to insecticide resistance management, and to frame key epidemiological questions. For

Figure 3. Illustration of insecticide resistance outbreaks. @@TODO explanation.

example, we would like to begin to build a picture of where and when local conditions have favoured the evolution of insecticide resistance, and whether those conditions are relatively patchy (and hence outbreaks are mainly localised) or whether conditions are consistent over broad areas (and hence can support a spreading outbreak). We would also like to know which mosquito populations are sufficiently connected to enable outbreak spread, and if there is any consistent pattern to the direction of spread. This information could be relevant to discussions about how resources for insecticide resistance management might be targeted, what strategies are appropriate in which settings, and where and when insecticide resistance management needs to be coordinated between different countries and/or at different levels of administration.

For clarity, we also define the concept of an insecticide resistance outbreak formally in terms of coalescent theory, as a collection of lineages (1) sharing a resistance driver allele by descent, (2) coalescing more recently than the onset of insecticide pressure, and (3) having increased in frequency because of positive selection due to insecticides. This definition is illustrated for four hypothetical outbreaks in Figure 3. Because mosquitoes are sexually recombining, genealogical trees vary along the genome, and so we define resistance outbreaks with respect to a specific gene locus, which for the present study is codon 995 within the *Vgsc* gene. Note that separate outbreaks may be driven by the same resistance allele, and this can occur if multiple mutational events occur after the introduction of insecticides (Figure 3, outbreaks 1 and 2), or if a resistance allele is present in mosquito populations as standing variation prior to insecticide use (Figure 3, outbreaks 3 and 4). Here we are primarily concerned with whether outbreaks are localised or spreading, because this has immediate epidemiological relevance. We do not attempt to infer whether separate outbreaks with the same driver allele arose via standing variation or new mutations, however this is an interesting biological question to address in future studies. As a technical note, there is a simple correspondance with terminology conventionally used in the population genetics literature to describe selective sweeps. At a given gene locus, a hard selective sweep gives rise to a single resistance outbreak, and a soft selective sweep gives rise to multiple resistance outbreaks.

310 Outbreak analysis from haplotype age

311 As described above, haplotype data from genome regions both within and flanking the
 312 *Vgsc* gene provide a higher resolution for reconstructing recent historical events. To lever-
 313 age this information, we used a heuristic approach to estimate the time to most recent
 314 common ancestor (TMRCA) or “age” for each pair of haplotypes in our dataset, centering
 315 the analysis on *Vgsc* codon 995. For each pair of haplotypes, we estimated the length
 316 of the region shared identical by descent (IBD), and the number of mutations that have
 317 accumulated since the most recent common ancestor. We then combined these two pieces
 318 of information to produce a point estimate for the haplotype age (Methods). We studied
 319 the overall distribution of pairwise haplotype ages (Figure 4), and used hierarchical clus-
 320 tering to construct a dendrogram and visualise the overall age structure (Figure 5). We
 321 caution that although the estimated ages are in units of generations, these estimates have
 322 not been calibrated, and there is substantial uncertainty regarding both the mutation and
 323 recombination rate parameters. The ages therefore should not be interpreted as reliable
 324 absolute values, but they can be compared to each other to investigate the relative age of
 325 different events.

326 A key feature of the overall age distribution is that it is bimodal, with a minor mode of
 327 haplotypes coalescing recently, and a major mode coalescing further in the past (Figure
 328 4). This is expected at an insecticide resistance locus experiencing one or more resistance
 329 outbreaks. Within each outbreak, all haplotypes share a very recent common ancestor,
 330 but between outbreaks and among haplotypes without any resistance allele, haplotypes are

Figure 4. Haplotype age distribution. @@TODO caption.

331 more distantly related, and the distribution of ages is influenced by mosquito population
 332 size and other demographic factors. In particular, mosquito populations generally have
 333 a large effective population size (@@REF Ag1000G), and so in the absence of selection,
 334 haplotypes are expected to coalesce slowly. The bimodal age distribution is not due to
 335 geographical population structure, because the same bimodality is observed within several
 336 populations. We take the midpoint between these two modes as an estimate for the earliest
 337 time of onset of selective pressure due to insecticides, and thus for the maximum age of
 338 a resistance outbreak. To identify haplotype clusters representing putative resistance
 339 outbreaks, we then cut the haplotype dendrogram at this maximum outbreak age (Figure
 340 5). Comparing this to previous analyses of haplotype structure based on genetic distance,
 341 we find clusters F1-F5 and S1-S3 recapitulated with close correspondence, and S4 and
 342 S5 merged into a single cluster. We label a new cluster “L@@” representing an outbreak
 343 driven by the I1527T allele in combination with one or the other V402L allele. We also label
 344 a cluster “L@@” capturing a set of haplotypes from Kenya carrying the M490I variant,
 345 although the fact that these haplotypes all share a recent common ancestor may be a
 346 reflection of the unusual demography of the Kenyan population which has experienced

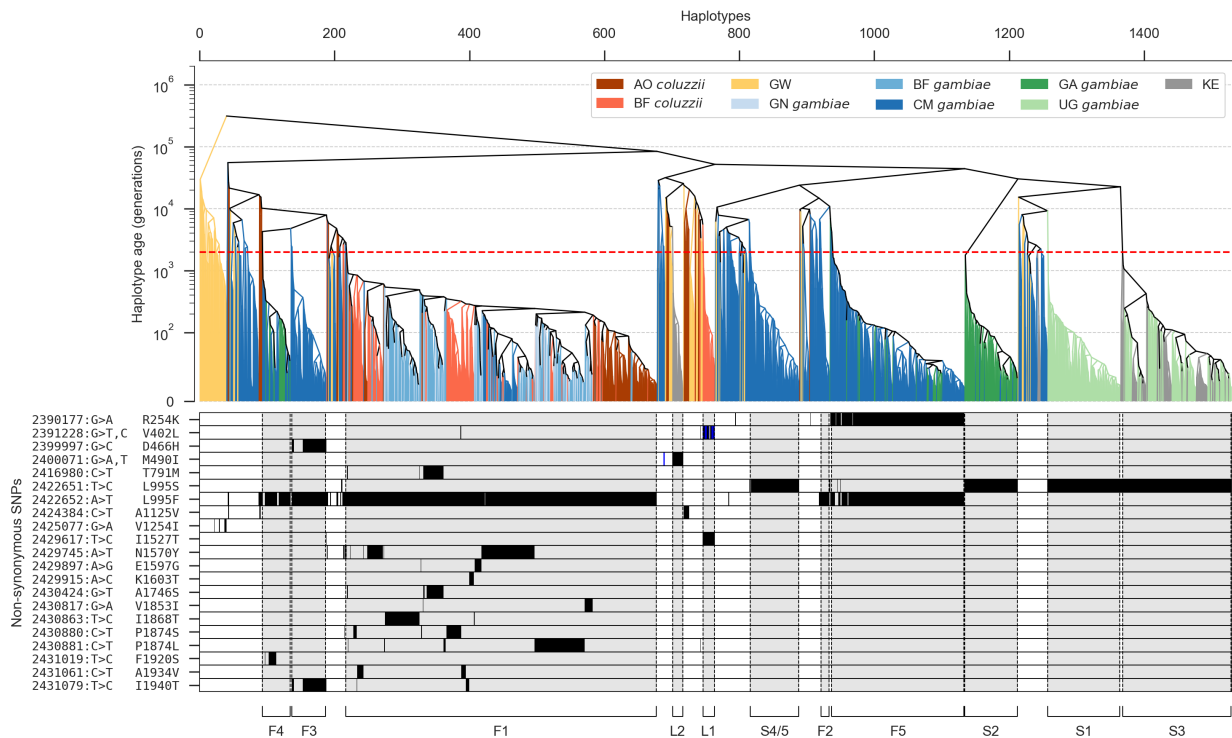

Figure 5. Clustering of haplotypes by age. @@TODO caption.

347 a severe population crash (@@REF) and not be due to recent selection for insecticide
 348 resistance. As in earlier analyses, clusters F1, F4, F5 and S3 all include haplotypes
 349 sampled from multiple geographical locations, and thus represent spreading outbreaks.
 350 Clusters F2, F3, S1, S2, S4/5 and L1 include only haplotypes from a single sampling
 351 location, and thus appear to represent localised outbreaks.

352 We then studied the distribution of haplotype ages within each spreading outbreak, to
 353 attempt to reconstruct information about the historical path of transmission of resistance
 354 alleles between locations. To do this, we grouped the haplotypes within each spreading
 355 outbreak by sampling location, and compared the distribution of haplotype ages both
 356 within and between locations. To aid in interpreting these data, we define three possi-
 357 ble spreading scenarios, being: (1) a directional spread from one population to another;
 358 (2) spread from an unsampled population into the sampled populations; and (3) a com-
 359 plex scenario involving multiple gene flow events. In Figure 6 we illustrate the expected
 360 genealogy and haplotype age distribution under each of these scenarios.

361 The clearest result was obtained for outbreak F1 (Figure 7). Within this outbreak,
 362 haplotypes from Cameroon and Angola are significantly younger than haplotypes from
 363 Burkina Faso and Guinea. The age distributions are consistent with an outbreak originat-
 364 ing in West Africa and subsequently spreading towards Cameroon and separately towards

Figure 6. Inferring history of spread from haplotype ages. @@TODO explain.

Angola. We were surprised that the age distributions for *An. gambiae* and *An. coluzzii* from Burkina Faso are very similar, despite the fact that previous studies have shown that introgression has occurred from *An. gambiae* into *An. coluzzii*. This may indicate that the initial introgression event happened during the early phases of the outbreak, but is also consistent with a complex history of multiple gene flow events between the species.

Outbreaks F4, F5 and S2 each involve haplotypes from both Cameroon and Gabon. Interpreting the age distributions for these outbreaks is difficult, because mosquitoes from Gabon were collected at a much earlier time point (2000) than mosquitoes from Cameroon (20@@). If our haplotype age estimates were well-calibrated, and we also had reliable estimates for the number of mosquito generations per year, then we might be able to adjust for this time difference, however we are not able to do so presently. An interesting feature of these outbreaks, however, is that we would expect haplotypes from Gabon to appear older due to the time of sampling, which is observed for outbreak S2 but not for F4 or F5. Indeed, S2 is at a high frequency among all Gabon haplotypes and a low frequency among Cameroon haplotypes, whereas the reverse is true for F4 and F5. These data suggest that F4 and F5 have spread from Cameroon towards Gabon, while S2 has spread in the opposite direction. A lot can happen in mosquito populations in @@N years, however, and these conclusions remain highly speculative pending further sampling from both locations.

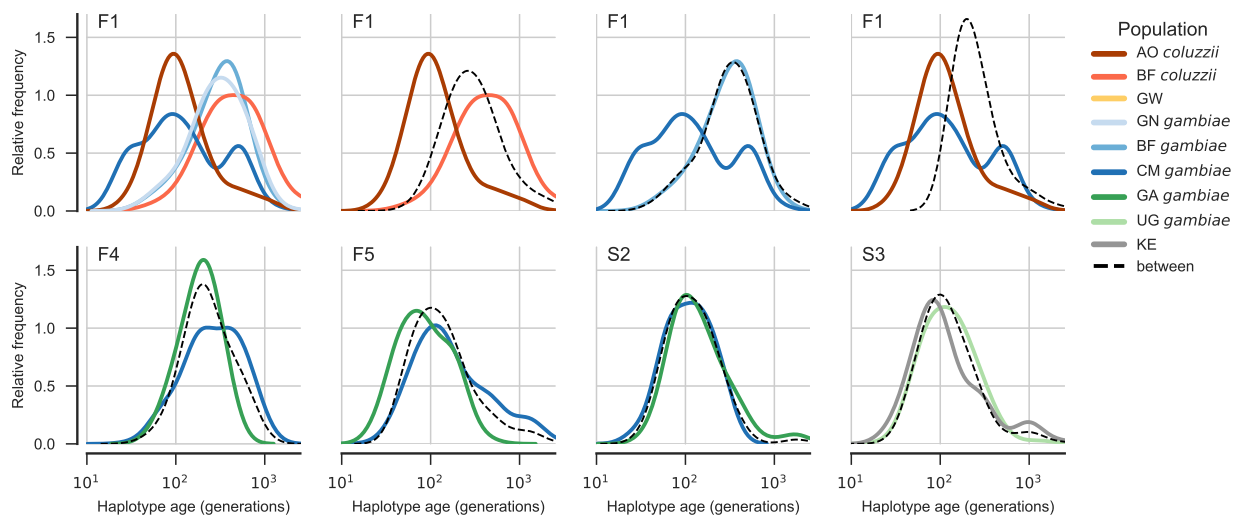

Figure 7. Haplotype age distributions within spreading outbreaks. @@TODO caption.

For outbreak S3 involving haplotypes from Uganda and Kenya, the age distributions do not suggest any clear direction of gene flow. This could reflect multiple gene flow events in either or both directions. However, another outbreak (S1) is localised in Uganda and represented within the Ugandan population at roughly equal frequency with S3. If transmission was occurring from Uganda towards Kenya, we might expect both outbreaks to have spread to Kenya. Thus the localisation of S1 suggests S3 has spread into Uganda from Kenya or another location. Again, this conclusion remains tentative and requires confirmation via further sampling.

To summarise these conclusions in a concise way, we have depicted the distribution and spread of resistance outbreaks via the map shown in Figure 8. We have plotted haplotypes from each sampling location as a pie chart. The overall size of each pie chart represents the number of haplotypes sampled, and coloured wedges within each pie represent the frequency of each resistance outbreak within the population. Coloured arrows are used to depict our inferences regarding the transmission paths for spreading outbreaks. Our conclusions regarding direction of spread for outbreaks F4, F5, S2 and S3 are tentative, and we indicate this with a question mark. Because of the relatively sparse geographical representation within the Ag1000G phase 1 dataset, and the fact that collections were not synchronized but span several years, we cannot be precise about the geographical

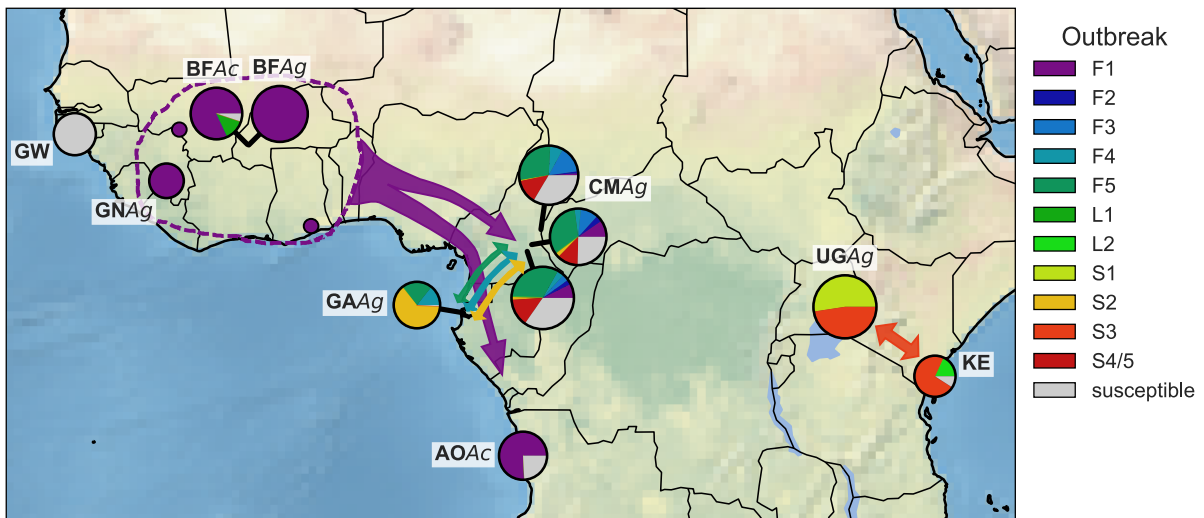

Figure 8. Geographical distribution of resistance outbreaks. @@TODO caption.
@@TODO explain Clarkon and Norris points.

origins of these resistance outbreaks. Even for outbreak F1 where we have clear evidence of spread from West Africa towards Central and Southern Africa, we have only sampled mosquitoes from Guinea and Burkina Faso, and the true source of the outbreak may not be either of these countries. We indicate this uncertainty regarding the outbreak source as a coloured area with a dashed border. This representation is imperfect, as is our knowledge regarding the sources and transmission paths of these outbreaks, but we hope this depiction may at least serve to stimulate further sampling, analysis and discussion, with the aim of improving our knowledge of resistance outbreaks for *Vgsc* as well as other insecticide resistance genes.

Design of genetic assays for outbreak surveillance

The insecticide resistance outbreaks we have identified here are undoubtedly ongoing, affecting many more mosquito populations than we have sampled in Ag1000G phase 1, and continuing to spread. In addition, other outbreaks may be occurring in populations that we have not sampled, or in populations we have sampled but since the sampling date. Whole-genome sequencing of individual mosquitoes clearly provides data of sufficient resolution to identify resistance outbreaks, and could also be used to provide ongoing outbreak surveillance. The cost of whole-genome sequencing continues to fall, with the present cost being approximately 100 GBP to obtain $\sim 30\times$ coverage of an individual *Anopheles* mosquito genome with 150 bp paired-end reads. Mobile sequencing using nanopore technology is also developing rapidly [29] and may be a realistic prospect for mosquito whole-genome sequencing within a few years. There is an interim period, however, during which it may be more practical to develop targeted genetic assays for outbreak surveillance that could scale to tens of thousands of mosquitoes at low cost. For example, both next-generation and mobile sequencing platforms can be used for amplicon sequencing, where specific genome regions are amplified and sequenced in highly multiplexed libraries [30, 31].

To facilitate the development of targeted genetic assays for *Vgsc* insecticide resistance outbreak surveillance, we have produced two supplementary data tables. In Supplementary Table 1 we provide a list of all biallelic SNPs discovered with high confidence in this study within the *Vgsc* gene and in the 100 kbp upstream and downstream flanking regions. To aid in PCR primer design, for each SNP we provide the flanking sequence for 250 bp

432 upstream and downstream of the SNP position, including information about polymor-
 433 phisms within these flanking regions. Not all SNPs are informative for detecting whether
 434 an individual mosquito carries a haplotype from a resistance outbreak, and we provide
 435 some summary statistics for each SNP to aid in the selection of the most informative
 436 SNPs. This includes allele frequencies within each of the outbreaks identified here, as well
 437 as for populations of susceptible haplotypes. We also provide the overall variance in allele
 438 frequencies, the information gain [32], and the Gini impurity [33] for each SNP. Note that
 439 recombination events are more likely at increasing distances upstream and downstream
 440 of the resistance variants under selection, and thus the most informative SNPs are found
 441 closest to the resistance variants within the gene (Figure 9). However, SNPs with some
 442 information gain are available throughout the gene and in flanking regions.

Figure 9. Informative SNPs for outbreak surveillance. **a**, Each data point represents a single SNP. The information gain value for each SNP provides an indication of how informative the SNP is likely to be if used as part of a genetic assay for testing whether a mosquito carries a resistance haplotype, and if so, which resistance outbreak it derives from. **b**, Number of SNPs required to accurately classify which outbreak a haplotype derives from. Decision trees were constructed using either the LD3 (left) or CART (right) algorithm for comparison. Accuracy was evaluated using 10-fold stratified cross-validation.

We suggest that the design of a genetic assay proceed by (1) performing an initial round of filtering to remove SNPs which are not informative (e.g., low information gain); (2) performing a round of primer design to remove SNPs for which primers are unlikely to be successful; (3) performing a full analysis of the remaining SNPs to select a subset that is sufficient to classify all outbreaks identified here, including some redundancy; (4) finalise primer designs for the chosen panel of SNPs. A possible methodology for step 3 would be to use an algorithm such as ID3 [32] or CART [33] to build a decision tree, although many other algorithms for building classifiers are also applicable. To aid in the development of a classifier, in Supplementary Table 2 we provide our classification for each of the 1530 haplotypes sampled here, along with the alleles carried by each haplotype for each of the SNPs included in Supplementary Table 1. To test the methodology, we constructed decision trees using either LD3 or CART algorithms, and using all available SNPs from within the *Vgsc* plus 20 kbp flanking regions as input features (i.e., assuming primers could be designed in all cases). Figure 9b shows the cross-validation scores obtained for trees constructed allowing increasing numbers of SNPs. This analysis suggests that it should be possible to construct a tree able to classify haplotypes from all 10 resistance outbreaks with >95% accuracy using 20 SNPs or less.

Recombination

To look for evidence that haplotypes have experienced recent positive selection, we performed an analysis of extended haplotype homozygosity (EHH) decay @@REF. We defined a core region spanning *Vgsc* codon 995 and an additional 4 kbp of flanking sequence (Methods). Within this core region, we found @@N distinct haplotypes at a frequency > 1% within the cohort, including core haplotypes representing each of the resistance outbreaks we identified above, and a further @@N core haplotypes not carrying any known or putative resistance allele for comparison. @@TODO finish this

Sandbox paragraph: @@TODO integrate or remove In this section we present analyses of recombination both within the *Vgsc* gene itself and on either flank. These analyses provide information about which haplotypes have experience recent selection, and an alternative view of how different haplotypes are related. They also provide information about where in the genome recombination events have occurred, and whether

473 these recombination events may have biased or otherwise influenced the outcome of analy-
 474 ses presented in other sections. EHH analysis first identifies collections of haplotypes with
 475 the same alleles at a core locus. The haplotypes within each collection are then compared,
 476 and the fraction of haplotype pairs that remain identical (EHH) is computed moving both
 477 up- and down-stream of the core locus. Recombination events break haplotype homozy-
 478 gosity, and so a slow decay of EHH indicates fewer recombination events, A collection of
 479 haplotypes where EHH decays more slowly provides evidence for positive selection on the
 480 core allele, Haplotypes that have risen rapidly in frequency due to selection will be younger
 481 on average, and thus the length of regions of homozygosity between pairs of haplotypes
 482 These analyses provide confirmation of which haplotypes have experience recent positive
 483 selection, as haplotypes that have recently increased in frequency will
 484 As mentioned earlier, analyses of haplotype structure based on genetic distance within

Figure 10. EHH decay. @@TODO caption

485 the fixed window of the *Vgsc* gene could be affected if recombination events occurred
 486 within the gene. Our analyses of haplotype age should be less affected by recombination,
 487 because they explicitly take recombination into account, estimating the positions at which
 488 recombination events have occurred to interrupt regions shared IBD between pairs of
 489 haplotypes. However, these analyses were based on a heuristic method for estimating
 490 recombination breakpoints, and there are several potential sources of error. To study
 491 the evidence for recombination within the genome region spanning the *Vgsc* gene, and
 492 provide some additional confirmation that our inferences regarding insecticide resistance
 493 outbreaks have not been affected by recombination or other sources of error, we performed
 494 an additional analysis of genetic distance between haplotypes. We first constructed a
 495 putative ancestral haplotype for each of the outbreaks we identified, by starting from
 496 the codon 995 position and separately moving upstream and downstream, assuming the
 497 major allele at each SNP bifurcation point represents the ancestral haplotype. We then
 498 computed the genetic distance (D_{XY}) between each of our sampled haplotypes and each
 499 of the inferred ancestral outbreak haplotypes, computing the distance in @@ overlapping
 500 windows of @@ bp across a 2 Mbp region spanning the *Vgsc* gene. The results for outbreaks
 501 F1-F5 are plotted in Figure 11, and outbreaks S1-S4/5 are shown in Figure ???. In these
 502 plots we expect that all haplotypes from a given outbreak should share very close genetic
 503 similarity ($D_{XY} \approx 0$) with each other and with the ancestral haplotype for that outbreak
 504 within the *Vgsc* gene itself, with an increasing number of haplotypes recombining away
 505 from the ancestral outbreak haplotype as we move away from the gene in either the
 506 upstream or downstream direction. Conversely, haplotypes from one outbreak should not
 507 share any close genetic similarity ($D_{XY} > 0$) with the inferred ancestral haplotype from
 508 a different outbreak, either within the *Vgsc* gene or in flanking regions.

509 The results for all outbreaks are largely consistent with this expectation. For this
 510 analysis we treated S4/5 as a single outbreak, as indicated by the haplotype age analysis,
 511 and we can gain some insight into why these two were split into separate clusters in earlier
 512 analyses. All haplotypes in the S4/5 outbreak share close similarity with the ancestral
 513 haplotype on both flanks of the *Vgsc* gene, but there is a short region of within the gene
 514 where a subset of haplotypes are diverged. This region of divergence accounts for the S4/S5
 515 split in earlier analyses. @@TODO explain @@TODO also note relatively low divergence

among F2, F3, F4 on upstream flank and explain

534 **Data collection and processing**

535 For detailed information on Ag1000g WGS sample collection, sequencing, variant calling,
536 quality control and phasing see [13]. In brief, *An. gambiae* and *An. coluzzii* mosquitoes
537 were collected from eight countries across Sub-Saharan Africa: Angola, Burkina Faso,
538 Cameroon, Gabon, Guinea, Guinea Bissau, Kenya and Uganda. From Angola just *An.*
539 *coluzzii* were sampled, Burkina Faso had samples of both *An. gambiae* and *An. coluzzii*
540 and all other populations consisted of purely *An. gambiae* except for Kenya and Guinea
541 Bissau, where species status is uncertain [13]. Mosquitoes were individually whole genome
542 sequenced on the Illumina HiSeq 2000 platform, generating 100bp paired-end reads. Se-
543 quenced reads were aligned to the [**An. gambiae**] AgamP3 reference genome assembly
544 [34]). Aligned bam files underwent improvement, before variants were called using GATK
545 UnifiedGenotyper. Quality control included removal of samples with mean coverage <=
546 14x and an accessibility map was employed following a similar approach to that used for
547 human data by The 1000 Genomes Project Consortium [35]). Various quality control filters

were applied to remove samples and SNPs with poor quality data. This process produced a call set containing 1000 SNPs genotyped in 765 wild-caught individual mosquitoes [13].

The Ag1000g variant data was functionally annotated using the SnpEff v4.1b software which allowed investigation of potential phenotype altering variants within *Vgsc* [36]. Non-synonymous *Vgsc* variants were identified as all variants in AGAP004707, 2L:2358158-2431617, with a SnpEff annotation of missense and an ALT allele frequency of >5% in at least one of the nine mosquito populations, with the exceptions of the multi-allelic SNP 2L:2400071 G>A which is shown despite only being found in *An. gambiae* from Cameroon at 0.4% frequency, as the G>T variant at the same position which causes the same codon change (M490I), is found above 5% frequency in Kenya. F1920S is included for continuity with recent *An. gambiae Vgsc* research [13]. A minimum ALT allele frequency was employed to discriminate towards variants that may be undergoing selective sweeps and against less informative low frequency alleles.

For ease of comparison with previous work on *Vgsc*, pan Insecta, in Table 1 we report codon numbering for both *An. gambiae* and *Musca domestica* (the species in which the gene was first discovered). The *M. domestica Vgsc* sequence (EMBL accession X96668 - [8]) was aligned with the *An. gambiae* AGAP004707-RA sequence (AgamP4.4 gene-set), using the Mega v7 software package [37]. A map of equivalent codon numbers between the two species can be download from the MalariaGEN website (include as supplementary data file?)- https://www.malariagen.net/sites/default/files/content/blogs/domestica_gambiae_map.txt.

Haplotypes for each chromosome of each sample were estimated (phased) using phase informative reads (PIRs) and SHAPEIT2 v2.r837 [38], see [13] supplementary text for more details. The SHAPEIT2 algorithm is unable to phase multi-allelic positions, therefore the two multi-allelic non-synonymous SNPs within the *Vgsc* gene (>5% ALT frequency in at least one population), altering codons V402 and M490, were phased onto the haplotypes using MVNcall v1.0 [39]. Conservative filtering had removed one of the three known insecticide resistance conferring *kdr* variants, N1570Y [9]. After manual inspection of the read alignment revealed that the SNP call could be confidently made, it was added back into the data set and then also phased onto the haplotypes using MVNcall. To evaluate the linkage disequilibrium (LD) of non-synonymous *Vgsc* mutations with the two

most widespread *kdr* resistance mutations (L995S/F), the D1 statistic was calculated using haplotypes.

Haplotype networks

Discerning the relationships between similar haplotypes can be difficult when using bifurcating trees as, inherently, the distance between the leaves at the tips (haplotypes) will be small. As these relationships may be informative of the history of selection, we utilised a network approach to elucidate them. We constructed haplotype networks using the median-joining algorithm [40] as implemented in a custom Python script available from <https://github.com/malariagen/agam-vgsc-report> Networks were rendered with the graphviz library and a composite figure constructed using Inkscape.
